Abstract

1 Adequate spatial and temporal estimates of NO₂ concentrations are essential for
2 proper prenatal exposure assessment. Here, we develop a spatiotemporal land
3 use random forest (LURF) model of the monthly mean NO₂ over four years in
4 a metropolitan area of Japan. The overall objective is to obtain accurate NO₂
5 estimates for use in prenatal exposure assessments. We use random forests to
6 convey the non-linear relationship between NO₂ concentrations and predictor
7 variables, and compare the prediction accuracy with that of a linear regression.
8 In addition, we include the distance decay effect of emission sources on NO₂
9 concentrations for more efficient model construction. The prediction accuracy of
10 the LURF model is evaluated through a leave-one-monitor-out cross validation.
11 We obtain a high R^2 value of 0.79, which is better than that of the conventional
12 land use regression model using linear regression (R^2 of 0.73). We also evaluate
13 the LURF model via a temporal and overall cross validation and obtain R^2
14 values of 0.84 and 0.92, respectively. We successfully integrate temporal and
15 spatial components into our model, which exhibits higher accuracy than spatial
16 models constructed individually for each month. Our findings illustrate the
17 advantage of using a LURF to model the spatiotemporal variability of NO₂
18 concentrations.

Keywords: air pollution, machine learning, distance decay effect, prenatal exposure, land use regression

1. Introduction

Exposure to air pollutants has been associated with adverse pregnancy outcomes in many epidemiological studies (Marozienne and Grazuleviciene, 2002; Rich et al., 2009; Faiz et al., 2012, 2013; Malmqvist et al., 2013; Fleischer et al., 2014; Stieb et al., 2016). Spatially and temporally adequate estimates of air pollutant concentrations are essential for proper exposure assessments in order to avoid potential misclassification or biased risk estimates. Land use regression (LUR) models have typically been used to satisfy this demand. In that approach, a linear regression model is developed incorporating both monitored concentrations, as the objective variable, and predictor variables that may affect the concentrations. The obtained regression model is then applied to unmonitored locations to estimate target air pollutant concentrations. LUR models are often applied for estimation of long-term averages, such as annual means of NO_2 (Beelen et al., 2013; Vienneau et al., 2013), NO_x (Beelen et al., 2013), $\text{PM}_{2.5}$ (Sampson et al., 2013), and PM_{10} (Vienneau et al., 2013). Further, monthly averages of NO_2 (Knibbs et al., 2014; Bechle et al., 2015; Proietti et al., 2016) and $\text{PM}_{2.5}$ (Beckerman et al., 2013), biweekly means of NO_2 (Ross et al., 2013; Proietti et al., 2016) and $\text{PM}_{2.5}$ (Ross et al., 2013), and daily NO_2 (Lee and Koutrakis, 2014; Cordioli et al., 2017), $\text{PM}_{2.5}$ (Di et al., 2016a), and PM_{10} (Alam and McNabola, 2015) concentrations have been estimated in some studies.

In many LUR studies, multiple linear regression has been applied to model pollutant concentrations (e.g., Beelen et al., 2013; Vienneau et al., 2013; Knibbs et al., 2014; Proietti et al., 2016). However, the relationship between the concentrations and potential predictor variables is often complicated and not necessarily linear. Another problem with linear regression is the difficulty in capturing the complex interactions between predictors. To handle these disadvantages,

46 machine learning has been successfully applied in some recent studies. For
 47 example, Di et al. (2016a) used a neural network to model daily $\text{PM}_{2.5}$ con-
 48 centrations across the continental United States with a cross validated R^2 of
 49 more than 0.8. Further, Di et al. (2016b) estimated the $\text{PM}_{2.5}$ constituents in
 50 the northern United States and obtained a cross validated R^2 of 0.6–0.8 for the
 51 major components. Brokamp et al. (2017) compared the performance of ran-
 52 dom forest and multiple linear regression techniques by applying them to the
 53 prediction of $\text{PM}_{2.5}$ elemental components, reporting that the random forest
 54 method was more accurate and precise.

55 Random forests, proposed by Breiman (2001), are a non-parametric statis-
 56 tical method that can handle non-linear relationships. The method is based
 57 on decision trees; it constructs each tree using a bootstrap sample of the data
 58 and splits each point in the tree according to the best of a subset of randomly
 59 chosen predictors at each point (Liaw and Wiener, 2002). This method can be
 60 applied to both regression and classification problems. The advantage of ran-
 61 dom forests is better performance compared to other machine learning methods
 62 such as support vector machines and neural networks (Liaw and Wiener, 2002).
 63 Moreover, random forests are robust against overfitting (Breiman, 2001). An-
 64 other advantage is that random forests have only two user-defined parameters:
 65 the number of variables in the subset at each node and the number of trees in the
 66 forest (Liaw and Wiener, 2002). Furthermore, the random forest cross validated
 67 accuracy is typically very insensitive to the values of these parameters (Liaw and
 68 Wiener, 2002).

69 Variable selection is an important step in LUR model construction that ex-
 70 cludes irrelevant or colinear predictors, which would otherwise generate unstable
 71 estimates (Brokamp et al., 2017). Several buffer sizes are usually defined to rep-
 72 resent the range of influence of the predictors. The concentration at the center
 73 of a buffer is regressed on the summed values in the buffer. This approach in-
 74 creases the number of potential variables to be considered by multiplying the
 75 number of variables by the number of buffer sizes. Given that some predictors
 76 represent emission intensity, the buffer approach assumes that emission sources

77 of the same intensity in a buffer equally contribute to the concentration at the
78 buffer centroid, regardless of the distance to the center. This assumption seems
79 to be contradictory to the air pollutant behavior; air pollutant concentrations
80 decrease with distance from its source due to diffusion. Vienneau et al. (2009)
81 introduced the distance decay effect to the LUR framework. They applied the
82 focal-sum approach and successfully modeled monitored NO₂ concentrations us-
83 ing the inverse distance-weighted sum of the emissions in the surrounding area.
84 The clear advantage of this approach is that a large number of potential buffer
85 sizes are not required. Furthermore, this approach is consistent with air pollu-
86 tant behavior. Note that some studies have already included inverse distance-
87 weighted variables, but several buffer sizes are simultaneously defined (Li et al.,
88 2012, 2013; Eeftens et al., 2016). Su et al. (2009) proposed a variable selection
89 method based on the distance decay effect, but did not use distance-weighted
90 predictors for LUR model construction. Extending the focal-sum with the dis-
91 tance decay effect to all potential predictors representing the emission intensity
92 constitutes a reasonable attempt at higher-efficiency model construction in the
93 LUR framework.

94 In this study, we develop a spatiotemporal land use random forest (LURF)
95 model of monthly mean NO₂ in a metropolitan area of Japan, where a birth co-
96 hort study has been conducted. The overall objective is to obtain accurate NO₂
97 estimates for use in prenatal exposure assessments. We use random forests to
98 capture the non-linear relationship between the NO₂ concentrations and predic-
99 tors. We consider the distance decay effect and apply a focal-sum approach to
100 the preparation of potential predictors with the aim of constructing the model
101 in the most efficient manner. We then evaluate the developed model using cross
102 validation and compare the performance of our model to that of the LUR model
103 using multiple linear regression and the same potential variables. Furthermore,
104 we discuss the advantages of a spatiotemporal model using random forests.

105 **2. Methods**

106 *2.1. Study area*

107 The Japan Environment and Children’s Study (JECS) is an ongoing nation-
108 wide birth cohort study implemented in January 2011 to evaluate the effects
109 of various environmental factors on child health and development (Kawamoto
110 et al., 2014). The JECS incorporates 15 regions across Japan in which preg-
111 nant women were recruited as study participants from 2011 to 2014 (Kawamoto
112 et al., 2014). Our study area included one of the JECS regions, Amagasaki City
113 (135.4°E, 34.7°N), and its surrounding area (Fig. S1). Amagasaki City has a
114 population of 430,000 and an area of 50 km². We extended the study area out-
115 side Amagasaki City by approximately 20 km, because only three observations
116 were available in the city. The study area covered approximately 46 km from
117 east to west and 55 km from north to south. This area, containing more than
118 10 million inhabitants, includes mega cities such as Osaka and Kobe. In the
119 future, we intend to conduct an exposure assessment in Amagasaki City.

120 *2.2. Air quality measurements*

121 We obtained air quality observations from 2011 to 2014 from the database
122 of the regulatory monitoring network in Japan. Network data are collected
123 and stored in this database by the Japanese Ministry of Environment. Data
124 quality is controlled according to the uniform national standard. The monitoring
125 stations are categorized into two types, automobile exhaust stations and general
126 environment stations, and are located according to their specific purpose. That
127 is, the former are located at intersections or roads with heavy traffic to monitor
128 severe air pollution, i.e., at hot spots. The latter are located such that they
129 are not directly affected by specific emission sources, in order to measure the
130 representative concentrations over a certain spatial extent. Accordingly, we
131 utilized observations from general environment stations only in this work. In
132 our study area, stations of this type are located at various distances from major
133 traffic roads (highway, primary, and secondary roads defined in the road network

data used in this study, as described below). Specifically, some monitoring sites are located close to major roads (the shortest distance is less than 20 m), whereas others are positioned very far from major roads (the shortest distance is more than 2 km). Further, note that the shortest distances from the monitoring sites to the major roads are distributed relatively homogeneously, as apparent from Table S1. We believe the observations at the latter stations well represent the concentrations in our study area, covering not only the urban background, but also the areas where the concentrations are influenced by traffic.

We used hourly mean concentrations to calculate the monthly mean values over a four-year period. Data with a temporal coverage of more than 80% on both daily and monthly bases were used for the analysis to ensure that it was temporally representative. The number of general environment stations under operation for NO₂ monitoring was 81 in 2014, but only three monitors were located in Amagasaki City.

Fig. 1 presents a plot of the monthly mean concentrations used in this study. The seasonal variation in concentration is clear: high in winter and low in summer.

Figure 1: Box plot of monthly NO₂ concentrations used in this study.

151 2.3. Data set

152 We selected data sets considering key factors affecting the spatial distribution
153 of air pollutants, including emission, advection, and deposition. Some of the
154 gridded data were resampled to conform to an origin and resolution of 500 m.
155 The built-up area ratio in a grid cell was calculated from land use data. The
156 green area ratio was obtained by summing the ratio of rice fields, agricultural
157 fields, and forest from the land use data.

158 We calculated the road length in a grid cell using road network data instead
159 of readily available road length data. This is because the spatial resolution of the
160 publicly available road length data is, to the best of our knowledge, coarser than
161 that of our 500-m resolution grid. In the road network data set, road types are
162 classified into three categories: highway, primary, and secondary; in this study,
163 the road length in a grid cell was calculated for each of these categories. We
164 also calculated the shortest distances from a grid cell centroid to each road type
165 and employed these values as predictors.

166 We included the emission intensities of large point sources as a predictor.
167 The emission intensity was obtained from EAGrid2010 (Fukui et al., 2014),
168 which is a widely used emission inventory in Japan, being specially compiled for
169 air quality models. This inventory has a spatial resolution of 1 km and a tempo-
170 ral resolution of 1 month. We excluded the emission intensity of transportation
171 in the EAGrid2010 database, because the road length used as a transportation
172 proxy had a finer spatial resolution of 500 m.

173 As for meteorological parameters, we utilized daily mean observations of pre-
174 cipitation and wind speed from the Automated Meteorological Data Acquisition
175 System (AMeDAS), the monitoring stations of which are densely and homoge-
176 neously distributed throughout the country. We calculated the monthly means
177 and interpolated them using ordinary kriging to obtain gridded data of monthly
178 means with a 500-m resolution.

179 Satellite-derived NO_2 data have a wide temporal and spatial coverage. This
180 feature is useful for constructing a spatiotemporal LUR model. In recent stud-
181 ies, the NO_2 tropospheric column abundance has been introduced as a predictor

variable for LUR, and good prediction performance has been reported (Knibbs et al., 2014; Bechle et al., 2015). The Ozone Monitoring Instrument (OMI) flown on the Aura satellite measures the spectrum in the ultraviolet/visible wavelength range with a very high spatial resolution and daily global coverage (Levelt et al., 2006). We obtained the daily NO₂ tropospheric column abundance from the version 3.0 release of the gridded OMINO2d product and calculated the monthly means. Because the spatial resolution of OMI NO₂ data is 0.25° (approximately 25 km) and coarse compared to our prediction grid size of 500 m, we simply disaggregated these data into a 5-km-resolution data set through bilinear interpolation. Details of the data sets are presented in Table S2.

2.4. Implementation of distance decay effect

To consider the distance decay effect, we applied the focal-sum approach (Vienneau et al., 2013) to the potential predictor variables that indicate emission intensity: land use, road length, population, and large point sources. In this approach, a moving window passes over all grid cells. The values inside the window are multiplied by the corresponding factors defined by the inverse distance to the central cell. The sum of the products is assigned to the central cell (Vienneau et al., 2013). This new value is the distance-weighted measure for the central cell. Previously, Vienneau et al. (2013) examined various window shapes and weighting factors, and reported similar accuracies for NO₂ concentration estimates. Here, we used a simple circular window and the squared inverse distance as a weighting factor, which was obtained by:

$$w = \frac{1}{(d+1)^2}, \quad (1)$$

where w is the weighting factor and d is the distance (km) from the central cell. We used $d+1$ rather than d in the denominator to avoid division by zero. The central cell has a value of 1. Note that the radius of the moving window can be set to infinity to include all emission sources; however, for practicality, we set the window radius to 15 km so that the minimum weighting factor was

approximately 1 % of the largest factor at the central cell. Other variables such as OMI NO₂ and meteorological parameters were supplied without implementation of the focal-sum process, because these variables do not represent emission intensity.

We also included the month and year as predictor variables in order to capture the temporal variations. These variables were treated as categorical variables. The monthly or annual trends were not considered. Table 1 presents the potential predictor variables.

Table 1: Potential predictor variables.

Predictor variables	Unit	Direction of effect
Built-up area ratio	unitless	+
Green area ratio	unitless	-
Population	number	+
Road length, highway	km/km ²	+
Road length, primary road	km/km ²	+
Road length, secondary road	km/km ²	+
Distance to highway	m	-
Distance to primary road	m	-
Distance to secondary road	m	-
Point source	Tg/year	+
OMI NO ₂	10 ⁻¹⁵ molecules/cm ²	+
Precipitation	mm/h	-
Wind speed	m/s	-
Month	none	not specified
Year	none	not specified

2.5. Land use random forest model

We constructed a spatiotemporal LURF model using the variable selection method proposed by Genuer et al. (2015). First, we ran an initial random forest with all potential variables, repeating it 50 times. The potential predictors were

222 then ranked by sorting the variable importance measure, averaged over the
 223 repetitions, in descending order. Random forest models were constructed with
 224 k first predictors for $k=1,2,\dots, m$, where m is the number of potential predictors,
 225 with each being repeated 25 times. We selected the model with the smallest out-
 226 of-bag error averaged over the repetitions for each predictor combination. Next,
 227 the variables in the selected model were sequentially introduced to the random
 228 forest model in order of variable importance, as determined in the first step. A
 229 variable was retained in the model only if the out-of-bag error decreased by a
 230 greater degree than the averaged variations of the noisy variables removed in the
 231 second step. The variables in the last model were selected. During this process,
 232 the number of variables in the subset at each node (m_{try}) was set to $2p/3$, where
 233 p is the number of predictor variables in the entire data set. Finally, the random
 234 forest model with the selected predictors was optimized for m_{try} . The number
 235 of trees ($ntree$) was consistently set to 500. The other parameters were set to
 236 the default values of the ranger package (Wright and Ziegler, 2017) used in this
 237 study, including a minimum node size of 5. The model R^2 was calculated as
 238 $1-MSE/var(Y)$ where Y is the observed values and MSE is the mean of the
 239 out-of-bag errors for all the prediction points (Brokamp et al., 2017).

240 2.6. Land use regression model

241 We constructed a spatiotemporal LUR model based on a supervised step-
 242 wise selection procedure used to develop LUR models for NO_2 in Europe (Beelen
 243 et al., 2013). The potential predictor variables of the LUR models were identical
 244 to those of the LURF model presented in Table 1. We specified the direction of
 245 effect according to the relationship between the pollutants and predictor vari-
 246 ables (Beelen et al., 2013). First, univariate regression analyses were conducted
 247 for all potential predictors. The initial regression model was constructed using
 248 the predictor giving the highest adjusted R^2 with the defined direction of effect.
 249 Second, the remaining variables were consecutively tested through addition to
 250 the model. The predictor with the highest additional increase in adjusted R^2
 251 was retained, if the following conditions were fulfilled: 1) the predictor increased

the adjusted R^2 by more than 0.01; 2) its coefficient conformed to the specified direction of effect for the variable; 3) it did not change the direction of effect for the predictors already in the model. This variable test was repeated until there were no more variables that increased the adjusted R^2 by more than 0.01. Third, variables with a p -value greater than 0.1 were removed and the regression model was reconstructed using the retained variables. For categorical variables, a likelihood ratio test was conducted between models with and without the variable; hence, a p -value was obtained. Finally, the variance inflation factors (VIF) were checked to determine whether they were less than or equal to 3. In addition, the Cook's D statistics for all the observations were assessed to determine whether they were less than or equal to 1.

The pollutant concentrations were transformed to a natural logarithmic scale before analysis and the predictions were back-transformed after analysis. This procedure has the advantage that the predicted concentrations are positive, which is not the case when analyses are performed without transformation (Beelen et al., 2009).

2.7. Evaluation

We performed leave-one-monitor-out cross validation to assess the accuracy of the obtained models. The observed data were removed from one location for the entire period and the model was constructed using the remaining location data. This process was repeated for the remaining locations. The R^2 and root mean squared error (RMSE) between the predicted and measured values were computed as indicators of the prediction accuracy. Note that the RMSE values are desired to be as small as possible. We refer to this validation process as spatial cross validation. We also conducted temporal and overall cross validations. For the temporal cross validation, monitoring data were omitted for a particular month and the model was constructed using the remaining 47 months of data. Concentrations at the monitored locations in the selected month were then predicted using the model. This process was repeated for the remaining 47 months and R^2 and RMSE values were computed. For the overall cross validation, we

282 performed 5-fold cross validation. The observations were evenly divided into
 283 five splits at random. One observation split was omitted and the model was
 284 constructed using the remaining four observation splits. The concentrations
 285 at the times and locations of the selected observations were predicted by the
 286 model. This process was repeated for the remaining four splits. The R^2 and
 287 RMSE values were computed. For a fair comparison, the splits were identical
 288 for the LURF and LUR model evaluations. These statistical indicators were
 289 also calculated separately for monitoring locations in Amagasaki City. We refer
 290 to these stations and all stations in the study area as "inside stations" and "all
 291 stations", respectively. We also construct LURF and LUR models using all the
 292 potential predictors and conducted spatial cross validation in order to compare
 293 R^2 values with the corresponding ones obtained for the LURF and LUR model
 294 constructed using the selected variables (i.e., the final models) for a sensitivity
 295 analysis.

296 To assess the advantages of a spatiotemporal LURF model over a spa-
 297 tial LURF model, we constructed spatial models for each month; thus, 48
 298 monthly models were obtained. We then individually evaluated the spatial
 299 models through leave-one-monitor-out cross validation and calculated R^2 and
 300 RMSE values for each model. We constructed the spatial models with the same
 301 variables as those for the spatiotemporal model, except for month and year. We
 302 did not apply the variable selection process to the monthly models because of
 303 the computation costs. For the temporally variable predictors, we extracted
 304 the data from the corresponding year and month. We also constructed and
 305 evaluated spatial LUR models in the same manner for comparison purposes.

306 We statistically evaluated the differences between the spatiotemporal LURF
 307 and LUR models using a paired t -test and F -tests (Hengl et al., 2015). The
 308 paired t -test evaluates whether two models have the same mean errors (ME).
 309 The F -test evaluates whether two models have the same variance, i.e. RMSE,
 310 assuming that the MEs are the same.

311 2.8. Computation

312 All spatial and statistical calculations were performed using R statistical
313 software (3.4.3) (R Core Team, 2017), with the raster package (Hijmans, 2016)
314 for integration and construction of the potential predictor variables, and the
315 ranger package (Wright and Ziegler, 2017) for implementation of the random
316 forests.

317 3. Results

318 3.1. Spatiotemporal LURF model

319 Fig. 2 shows the variable importance plot of the final LURF model. In this
320 plot, the selected variables are listed in order of importance from top to bottom.
321 The horizontal axis represents the measure of importance. The green area ratio
322 is the best predictor. Satellite-based NO₂ is the second most influential variable,
323 followed by point emission sources and month, reflecting the clear seasonality
324 in the concentrations, as shown in Fig. 1. Highway road length and distance
325 to highway are also important covariates. The remaining variables, including
326 the meteorological parameters, built-up area ratio, and year, are ranked as less
327 important. The variables removed from the model by the variable selection
328 process are primary road length, secondary road length, distance to primary
329 road, distance to secondary road, and population. The model R^2 value is 0.92.

330 Scatter plots of the predicted and observed concentrations obtained through
331 cross validation are presented in panels (a)–(c) of Fig. 3. Panels (a) and (d), (b)
332 and (e), and (c) and (f) show the results of the spatial, temporal, and overall
333 cross validation, respectively. The dot color indicates the point density in the
334 plot: red and green indicate higher and lower density, respectively. The triangles
335 indicate the results for inside stations. R^2 and RMSE values are given in each
336 panel for all stations and inside stations.

337 The R^2 values for the spatial and temporal validation are 0.79 and 0.84,
338 respectively. The RMSE values are 2.6 and 2.2 (ppb), respectively. A high R^2
339 value of 0.92 is obtained for the overall cross validation, with an RMSE value

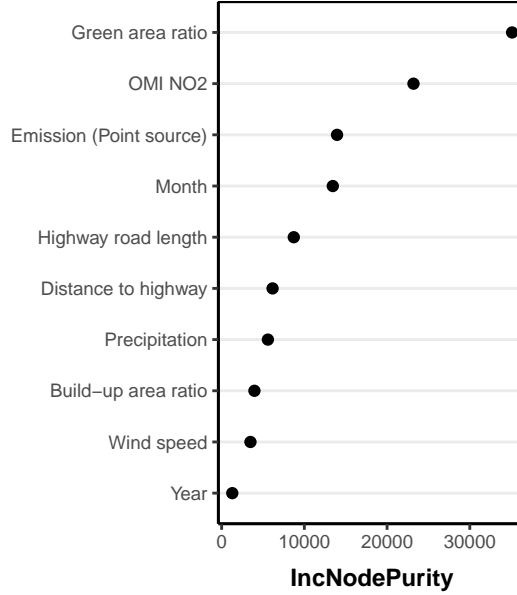

Figure 2: Variable importance plot for the LURF model. The variables are listed in order of importance from top to bottom. The horizontal axis represents the measure of importance.

of 1.6 (ppb). Compared to the corresponding values for all stations, the R^2 values for the inside stations are lower for the overall and temporal cross validations, and higher for spatial cross validation. The RMSE values are similar for all stations and inside stations for the three types of cross validation. The LURF model constructed using all the potential predictors gives a cross validated R^2 value of 0.79 and RMSE of 2.6 (ppb), which are almost identical to those obtained for the final LURF model using the selected variables.

The statistical indicators of the spatial LURF models for 48 months are presented as box plots in panels (a) and (c) of Fig. 4, showing the R^2 and RMSE values, respectively. The indicators of the spatiotemporal LURF model are also presented for comparison, as a horizontal line on the left side of each panel. The median R^2 values for the spatial models are 0.73 and 2.4 (ppb), respectively, indicating that the spatiotemporal model outperforms the spatial models in terms of R^2 .

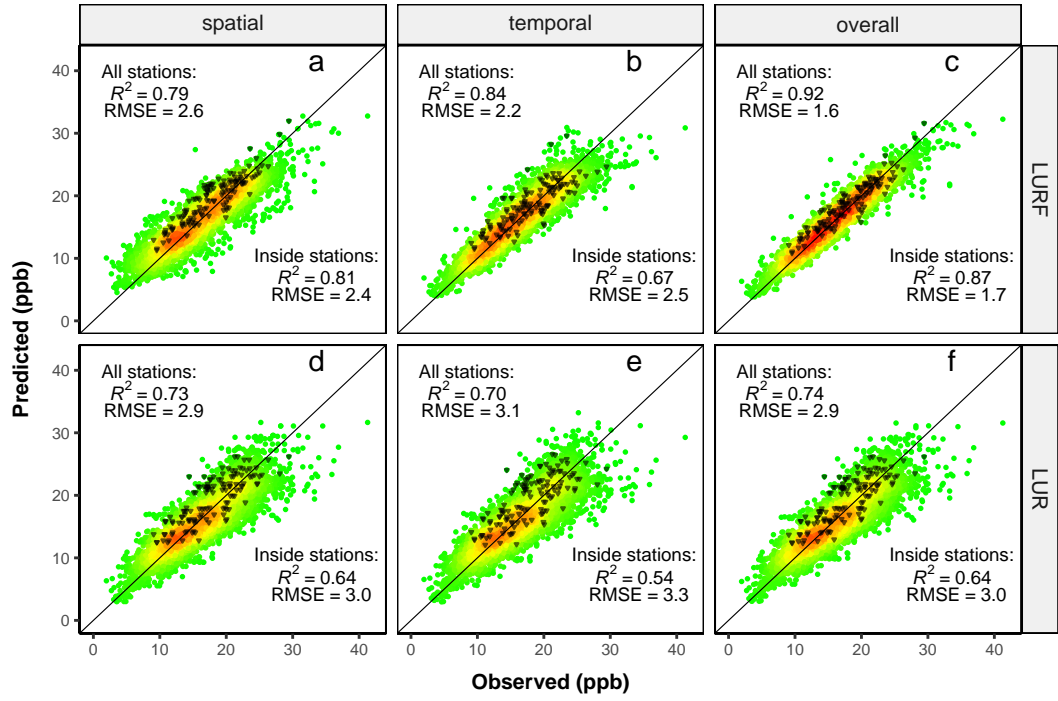

Figure 3: Scatter plots of predicted and observed concentrations obtained from cross validation. (a)–(c) and (d)–(f) show LURF and LUR results, respectively. (a) and (d), (b) and (e), and (c) and (f) show the spatial, temporal, and overall cross validation results, respectively. The red and green colors indicate higher and lower point density, respectively. The triangles indicate the results for the inside stations.

Figure 4: Box plots of statistical indicators for spatiotemporal and spatial models. (a) and (b) show R^2 values and (c) and (d) show RMSE values. (a) and (c), and (b) and (d), present LURF and LUR results, respectively.

3.2. Spatiotemporal LUR model

The selected variables in the final model are the green area ratio, month, and highway road length. These predictors are ranked as important in the LURF model, but other important predictors such as OMI NO₂ and point emission sources are discarded. The model adjusted R^2 value is 0.77. Table S3 presents the details of the final spatiotemporal LUR model.

Scatter plots of the predicted and observed values obtained via cross validation are presented in panels (d)–(f) of Fig. 3. A R^2 value of 0.73 is obtained for the spatial cross validation. The R^2 and RMSE values are similar between the three cross validation results. A comparison of the results from the inside stations against all stations shows that the R^2 values for the former are smaller than those for the latter, while the RMSE values are similar. The LUR model

constructed using all the potential variables gives a cross validated R^2 value of 0.76 and RMSE of 2.8 (ppb), which are similar to those obtained for the final LUR model using the selected variables.

The R^2 and RMSE values obtained for the 48 spatial LUR models are presented as box plots in panels (b) and (d) of Fig. 4. The median R^2 is 0.70, which is slightly lower than that of the spatiotemporal LUR model. The median RMSE is smaller.

3.3. Comparison

The spatial cross validated R^2 value of 0.79 for the spatiotemporal LURF model is higher than that of the spatiotemporal LUR model. The paired t -test results show that the differences in ME between LURF and LUR are not statistically significant ($p > 0.01$). The F -test result indicates that the differences in RMSE between the two models are statistically significant at the 1% level. In both the temporal and overall cross validation results, the differences in RMSE between the two models are significant at the 1% level, while the differences in ME are not significant ($p > 0.01$). The temporal and overall cross validated R^2 values for the LURF model are 0.84 and 0.92, respectively, which are higher than those for the LUR model, at 0.70 and 0.74, respectively. These results show that the LURF model outperforms the LUR model.

We report higher cross validated R^2 values and similar RMSE values for the spatiotemporal LURF model than for the spatial LURF models (Figs. 4(a) and (c)). Meanwhile, the R^2 and RMSE values are marginally higher and larger for the spatiotemporal LUR model than for the spatial LUR models, respectively, as shown in Figs. 4(b) and (d). A comparison of the spatial LURF and LUR models shows that the median R^2 of the LURF models is slightly higher and the median RMSE is slightly smaller than those of the LUR models, although the F -test result indicates that the differences in RMSE are not statistically significant at the 1% level ($p=0.02$).

394 3.4. Mapping

395 Fig. 5 is a prediction map of the NO₂ concentrations averaged over the study
 396 period. This map was produced by averaging the monthly estimations over
 397 the four-year study period, and disaggregated to 100-m resolution via bilinear
 398 interpolation for presentation purposes.

Figure 5: Prediction map of four-year mean concentrations of NO₂, disaggregated to 100-m resolution by bilinear interpolation for presentation purposes.

399 4. Discussion

400 We developed the spatiotemporal LURF model of NO₂ reported in this study
 401 to predict the monthly mean NO₂ concentrations for the consecutive four-year
 402 study period. Our spatiotemporal LURF model is accurate, with a spatial cross
 403 validated R^2 and RMSE value of 0.79 and 2.6 (ppb), respectively. No significant
 404 over or under estimation is apparent in the cross validation results, as shown

405 in Fig. 3. Thus, when applying of our LURF model to exposure assessments,
 406 the estimations at participant addresses can be expected to be accurate. The
 407 overall cross validation provides better R^2 and smaller RMSE values than the
 408 temporal and spatial cross validation. This suggests that we have successfully
 409 combined the temporal and spatial components in our spatiotemporal LURF
 410 model. The overall cross validated R^2 is almost identical to the model R^2 ,
 411 while the spatial and temporal cross validated R^2 are smaller. This indicates
 412 that our LURF model is not over-fitted overall, but is over-fitted especially
 413 in the spatial aspect. The LURF model constructed with all the potential
 414 variables shows almost identical cross validated R^2 and RMSE values to those
 415 for the final LURF model, which indicates that the variable selection process
 416 worked properly and successfully removed irrelevant variables. This result also
 417 demonstrates that the random forests are robust to noise variables (Breiman,
 418 2001).

419 Prenatal exposure assessment requires several NO_2 estimates at a fine tem-
 420 poral scale over a certain time period. Estimation models developed for this
 421 purpose should, therefore, be extended from two-dimensional space to three
 422 dimensions by adding a temporal axis. This can readily be achieved by con-
 423 structing individual two-dimensional (i.e., spatial) models for each time step,
 424 with no interaction between models. However, this involves cumbersome repeti-
 425 tion of the model construction process, including variable selection. A probably
 426 more popular solution is the temporal scaling approach, where spatial estimates
 427 for a particular time step are temporally scaled according to the measurements
 428 obtained from fixed continuous monitors (e.g., Slama et al., 2007; Ghosh et al.,
 429 2012). This approach assumes the spatial distribution pattern of air pollutants
 430 is constant over a certain period. Air pollutant concentrations are affected by
 431 meteorological parameters and/or emissions. Consequently, their spatial dis-
 432 tribution pattern changes over time according to the temporal changes in the
 433 spatial pattern of the influential factors. For instance, wind direction and wind
 434 speed change in time and space, as do emissions from different types of sources
 435 such as automobile and power plants, resulting in variation in the spatial pat-

tern of emissions over time. These spatial variations in the influential factors may be averaged out when mean concentrations over relatively longer timescales are considered. Thus, the scaling approach may be applicable to estimation of annual means, where the spatial pattern of the factors, and consequently the concentrations, are constant between years. However, it would be difficult to apply it to finer temporal scales when the spatial variation in the influential factors may not be averaged out and, accordingly, the spatial pattern of pollutant concentrations may temporally change. Our spatiotemporal model, on the other hand, is a three-dimensional model that implements a temporal component and integrates individual two-dimensional models into a three-dimensional model. This enables model construction and estimation without iteration for each time step. Further, this allows for temporal variation in the spatial distribution pattern. Hence, our spatiotemporal modeling is advantageous in its simplicity and flexibility. Clearly, estimation accuracy is of principal importance, and our spatiotemporal LURF model gives accurate predictions, which are better than those of spatial models. Therefore, our spatiotemporal LURF model has advantages over spatial models for estimating monthly mean NO_2 concentrations.

The estimation accuracy for inside stations is satisfactory, and the statistical indicators of the LURF model are similar to those for all stations, as shown in Fig. 3. This result indicates that our spatiotemporal LURF model has sufficient predictive power for future exposure assessment in smaller areas, despite having been developed based on larger areas.

With respect to the spatiotemporal LUR model, the statistical indicators obtained for the overall cross validation are comparable with those for the temporal and spatial validation, in contrast to the LURF model. This may be because random forests are powerful classifiers and can handle the temporal component, implemented as categorical variables in this study, more effectively than a linear regression. Hence, accurate predictions are provided by the spatiotemporal LURF model, which outperforms the spatiotemporal LUR model considered in this study. We note, however, that the implementation of the

temporal component as categorical variables may not be optimal for the LUR model and that better modeling of the temporal component could improve the performance of the spatiotemporal LUR. Our spatiotemporal LURF model consistently gives higher R^2 and significantly smaller RMSE values than the LUR model for spatial, temporal, and overall cross validation. This may be due to the ability of random forests to handle non-linear relationships between the predictors and outcome. On the other hand, the advantage of random forests is not as clearly demonstrated for the spatial models compared to the spatiotemporal models. One possible explanation is that we did not conduct a variable selection process for each monthly model, which would be required for a fair comparison of spatial models, for both LURF and LUR.

Although the prediction accuracy of the spatiotemporal LUR model is inferior to the spatiotemporal LURF models, the performance of the LUR model is still satisfactory, with an R^2 value of 0.73. The difference in the model and cross validated R^2 values is small, meaning that the spatiotemporal LUR model is not significantly over-fitted. The marginal difference in the cross validated R^2 and RMSE values between the final LUR model and the LUR model constructed using all the potential variables indicates that the variable selection process worked properly to discard unimportant predictors. The predictors prepared using the focal-sum with distance decay effect may contribute to the performance, although evaluation of the focal-sum approach is outside the scope of this study (a simple comparison of LURF and LUR models with and without the distance decay effect shows improvement in the model performance especially for LUR, as given in Table S4 and Fig.S3). We note, however, that the optimal weighting factor may be specific to each predictor depending on emission source characteristics, because the pollutants emitted from a high stack diffuse differently from those emitted from ground level sources like traffic. We require further investigation of the optimal selection of the weighting factor, other than the inverse distance squared approach, to improve the estimation accuracy, as well as a detailed evaluation of the approach. Nonetheless, in this study, we efficiently constructed land use models, reducing the effort required

498 for the variable selection process through this method.

499 Some predictors such as OMI NO₂ and point emission sources, which are
500 ranked as important for the LURF model, are not retained in the final LUR
501 model. While the LURF model selects variables based on the prediction error,
502 the LUR model chooses predictors based on R^2 . In addition, random forests
503 and linear regression are inherently different procedures. These differences may
504 explain the different predictors of the LURF and LUR models. Although satel-
505 lite NO₂ has been the focus of many LUR studies (e.g., Knibbs et al., 2014;
506 Bechle et al., 2015), OMI NO₂ was discarded in our LUR model. This may be
507 due to the coarse spatial resolution of the original data and/or our simple bilin-
508 ear interpolation approach for downscaling. In addition, we calculated monthly
509 means by simply averaging daily values and missing values are omitted from
510 the calculation. Consequently, an averaged value at a pixel with many miss-
511 ing daily values may not be an appropriate representation of a monthly value.
512 Kim et al. (2016) noted that the spatial resolution of OMI NO₂ is too coarse to
513 capture the spatial distribution in urban areas, with possible underestimation
514 at urban centers and overestimation outside. Satellite data at a finer resolution
515 could provide improved estimation accuracy for both LURF and LUR. In addi-
516 tion, Kuhlmann et al. (2014) developed a new gridding algorithm for OMI NO₂,
517 demonstrating that this method improves the accuracy of the obtained spatial
518 distribution of regional NO₂. Thus, a more accurate downscaling method is
519 required to improve the accuracies of LURF and LUR.

520 Brokamp et al. (2017) noted the difficulty in interpreting the results of ran-
521 dom forests. Unlike the LUR model, the LURF model lacks coefficients repre-
522 senting the directions and magnitudes of the effects of predictor variables on air
523 pollutant concentrations (Brokamp et al., 2017). This may be a trade-off for the
524 improved performance of random forests (Brokamp et al., 2017). However, LUR
525 models are not constructed based on a cause-consequence relationship, but on
526 correlation. When a variable equally contributes to concentrations in the area of
527 interest, the variable is most likely to be excluded in the resulting LUR model.
528 This is because it contributes to the concentrations, but not to the spatial dif-

ference in concentrations. Precipitation, for instance, is generally an influential parameter for NO₂ concentrations, but is not retained in our final LUR model. Therefore, the LUR model is unfit for elucidation of the physical or chemical processes of air pollutants. LUR model results may be useful for obtaining a basic understanding of the factors influencing the spatial distribution of air pollutants, but this model is not suitable for achieving detailed comprehension or performing quantitative analysis. Therefore, the difficulty in interpreting random forests can be more than compensated for by their prediction ability.

Although our spatiotemporal LURF model exhibits remarkable prediction accuracy, there are some limitations. Firstly, the high prediction accuracy may be specific to the monthly spatiotemporal LURF model. The high R^2 value of the overall cross validation may arise because the spatial variation pattern is relatively similar between months, with only the concentration level changing. This may also explain the finding that the month serves as a key predictor in our spatiotemporal LURF model. The spatial variation pattern may have higher variance on a finer temporal scale, e.g., weekly or daily, for which the temporal indicator variable is less important. Further investigation of the application of the LURF model to a finer temporal scale, which is preferable for prenatal exposure assessments, is required because we hope to extend our LURF model to a finer temporal scale as well as to a larger area and to other pollutants based on the results of this study. In addition, higher-spatial-resolution satellite data could play a more important role in improving the prediction accuracy of the LURF model on such a temporal scale. Secondly, concentration estimates at intersections or busy roads and their adjacent areas are likely to be underestimated. We constructed our spatiotemporal model without observations from automobile exhaust stations. These stations monitor potentially severe air pollution in limited areas (hot spots) at intersections or busy roads. Actually, the estimations at automobile exhaust stations via the spatiotemporal LURF model exhibit underestimations of 7.1 (ppb) on average (Supplementary material, pp-S7). The road structure in a metropolitan area is complicated, and primary or secondary roads are often located beneath elevated highways. The vertical and

horizontal positions of the monitors of the automobile exhaust stations at such locations may influence the observed pollution level. Monitors are sometimes installed in a building, and the measurements differ depending on the side of the building at which the monitor inlets are placed. This information is not available in the database used in this study. Moreover, it is difficult to model a three-dimensional structure using LURF or LUR. Although exclusion of automobile exhaust stations is a reasonable decision, use of our LURF model to predict concentrations in such potential hot spots would require caution.

Despite these limitations, in this study, we successfully developed a spatiotemporal LURF model for estimating accurate monthly mean NO_2 concentrations. We demonstrated the important advantages of using random forests to handle non-linearity and to capture temporal variation for the three-dimensional model. Our study also illustrates the potential for random forests to be incorporated into the LUR framework for epidemiological studies.
